(Dated: July 8, 2013)

We propose an easy-to-build easy-to-detect scheme for realizing Majorana fermions at the ends of a chain of magnetic atoms on the surface of a superconductor. Model calculations show that such chains can be easily tuned between trivial and topological ground state. In the latter, spatial resolved spectroscopy can be used to probe the Majorana fermion end states. Decoupled Majorana bound states can form even in short magnetic chains consisting of only tens of atoms. We propose scanning tunneling microscopy as the ideal technique to fabricate such systems and probe their topological properties.

PACS numbers: 03.67.Lx

The interest in topological quantum computing and non-abelian braiding has inspired many recent proposals to create Majorana fermions (MFs) in various experimental systems. Following Kitaev's seminal proposal<sup>1</sup>, many approaches have been considered including those based on topological insulators<sup>2,3</sup>; atoms trapped in optical lattices<sup>4-6</sup>; semiconductors with strong spin-orbit interaction in two and one dimension<sup>7-9</sup>; coupled quantum dots<sup>10,11</sup>; and those that combine magnetism of and superconductivity<sup>12-15</sup>. The aim of these approaches is to create a topological superconductor in which MFs emerge as the single excitations at the boundaries. Since MFs are its own antiparticles, they are predicted to appear in tunneling spectroscopy experiments as zero bias peaks<sup>16-19</sup>. Such peaks have been indeed observed in several experiments and interpreted as the signatures of MFs<sup>20-22</sup>. However, these experiments are not spatially resolved to detect the position of the MFs. Additionally, in many instances, the presence of disorder can result in spurious zero bias anomalies even when the system is not topological<sup>23,24</sup>. It is therefore desirable to identify easy-to-fabricate condensed matter systems in which MF can be spatially resolved and distinguishable from spurious disorder effects.

In this letter, we theoretically investigate conditions for which a chain of magnetic atoms on the surface of an s-wave superconductor can host MF modes. We explore the parameter space for which this system is topological and show that even relatively short chains made of only  $\sim 50$  atoms can host robust localized MFs. Our proposed structures can be fabricated using scanning tunneling microscopy (STM), which has previously been used to assemble structures of various shapes with tens of atoms using lateral atomic manipulation techniques<sup>25-27</sup>. Spatially resolved STM spectroscopy of such disorder-free chains can be used to probe the presence of MF end modes.

As shown in Fig. 1, we consider an array of magnetic atoms (such as atoms of 3d or 4f metals with a net magnetic moment) which are deposited on a single crystal surface of an s-wave superconductor (such as niobium (Nb) or lead (Pb)) and arranged into chains using the

STM. The interaction of a single magnetic moment with the superconductor gives rise to the so-called Yu-Shiba-Rusinov states<sup>28-31</sup> that have been previously detected from both 3d and 4f atoms on the surface of Nb and Pb using an STM<sup>32,33</sup>. The results of these previous experiments (with Gd and Mn deposited on Nb) agree well with model calculations in which the magnetic moment is assumed to be static<sup>32,34,35</sup>. In addition, recent spin polarized STM studies indicate that in magnetic arrays with  $\gtrsim 10$  atoms spin dynamics is greatly suppressed<sup>36</sup>. It is therefore reasonable to model moments of magnetic atoms as static classical spins. In general, magnetic moments in these chains can form various configurations including a spiral<sup>37</sup>.

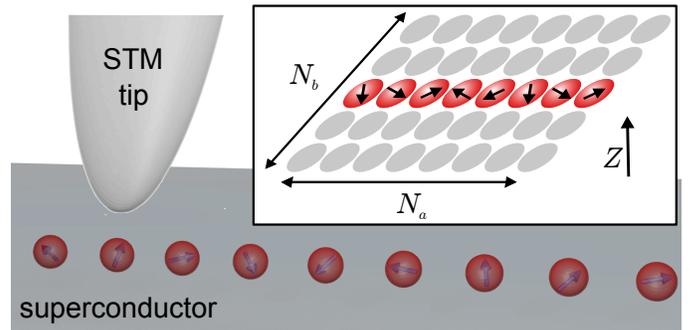

FIGURE 1. Schematic of the experimental setup. An array of magnetic atoms (red spheres) is assembled using scanning tunneling microscope on the surface of s-wave superconductor (gray background). The system is modeled by the two dimensional  $N_a \times N_b$  array in which magnetic atoms are embedded (inset). Throughout the paper we consider the case where magnetic moments are in the plane defined by  $N_a$  and  $Z$  direction.

To describe this system we use a two-dimensional tight-binding model Hamiltonian of an s-wave superconductor

with an array of magnetic atoms :

$$H = \sum_{\langle i,j \rangle \alpha} (t f_{i\alpha}^\dagger f_{j\alpha} + h.c.) - \mu \sum_{i\alpha} f_{i\alpha}^\dagger f_{i\alpha} + \sum_{n\alpha\beta} (\vec{B}_n \cdot \vec{\sigma})_{\alpha\beta} f_{n\alpha}^\dagger f_{n\beta} + \sum_i (\Delta_i f_{i\uparrow}^\dagger f_{i\downarrow}^\dagger + h.c.). \quad (1)$$

The operators  $f$  and  $f^\dagger$  correspond to electron annihilation and creation respectively,  $t$  is the hopping amplitude between adjacent sites  $\langle i,j \rangle$  of a *two-dimensional* lattice,  $\mu$  is the chemical potential,  $\Delta_i$  is the local superconducting gap associated with a host superconductor (equal to  $\Delta_0$  in the absence of magnetic atoms). The effective magnetic field  $\vec{B}_n$  gives rise to a local Zeeman energy on the atoms which are arranged in a *one-dimensional* array of sites  $\{n\}$ . We consider the case of identical atoms, i.e.  $|\vec{B}_n| = B$ . Throughout the paper we normalize all simulation parameters to the value of  $\Delta_0$ .

In order to obtain the two-dimensional gap profile in the vicinity of the atomic chain, we self-consistently solve the resulting Bogoliubov-de Gennes equations (BdG)<sup>38</sup>. We assume a constant on-site pairing coupling  $V$  for a grid of  $N_a \times N_b$  lattice sites in the middle of which  $N_a$  local magnetic moments with strength  $B$  are embedded (see<sup>39</sup> section 1 for details). The calculations are performed with open boundary conditions (BC) in the  $N_b$  direction, and both open and periodic BC in the  $N_a$  direction to show the presence or absence of MF at the end of the chain and to compute the Pfaffian index (Pf)<sup>1</sup>. Previous calculations showed that a single magnetic moment gives rise to a state inside the superconducting gap that has an energy close to  $\Delta_0$  for low  $B$ . As the value of  $B$  is increased the energy of this state is continuously tuned to zero<sup>34,35,40</sup>. This zero crossing is a signature of a quantum phase transition, at which the impurity site traps a single quasi-particle<sup>29,41</sup>. A similar phase transition occurs in the case of a few magnetic moments<sup>40,42</sup>. The transition obviously coincides with a change of the sign of the Pfaffian (computed in a periodic geometry) for the system, indicating a change of the fermion parity in the ground state. This is the characteristic signature of a topological non-trivial phase with MF end modes<sup>1</sup>.

An example of a transition into a topologically non-trivial phase for our atomic chain is illustrated in Fig. 2, which shows the lowest energy level and the Pfaffian as a function of  $B$  in the case of 96 magnetic moments. The angle between adjacent magnetic moments,  $\theta$ , plays a key role in determining whether this system is topological (see below), and has been assumed to be  $2\pi/3$  for the results shown in Fig. 2. The most important feature of this calculation is that in the parameter window  $2.2 < B/\Delta_0 < 3.45$ , in which for periodic BC in the  $N_a$  direction the Pfaffian is negative, and the spatial extent of the lowest excited state (Fig. 2b) (for open BC) shows the presence of MFs at the ends of the chain. This behavior can be contrasted with that of  $B/\Delta_0 = 2.1$  (Fig. 2c). In this case Pfaffian is positive and the lowest energy excitation is distributed approximately evenly along the chain.

A calculation of the local density of states (LDOS) as a function of energy shown in Fig. 2d clearly demonstrates that the topological case shows a zero bias peak associated with MF when tunneling at the end of the chain, while the middle of the system exhibits a mini-gap. In the non-topological phase sufficiently far away from the transition point, the system shows a clear gap throughout the chain and absence of zero energy end modes (Fig. 2e).

The emerging MF end modes considered here are localized on a very short length scale at the last few sites of the atomic chain. This situation can be contrasted to the proposals involving semiconductor nanowires in proximity with superconductors, where the coherence length of the superconductor sets the length scale for MFs<sup>9</sup>. The spatial extent of our MFs is reminiscent of the extent of the Yu-Shiba-Rusinov states created by single atoms, which have been shown both experimentally and theoretically to decay on length scales associated with the Fermi wavelength of a superconductor<sup>32,35</sup>. Note that these states do have long tails associated with the superconducting coherence length, however this decay is strongly enhanced with an algebraic decay pre-factor<sup>34,35</sup>.

While we used a self-consistent BdG calculation for realistic modeling of experimental situation, a more efficient approach to gain physical insight into this system is to consider an effective 1D model of magnetic atoms on superconducting sites, which is just the  $N_b = 1$  limit of our 2D model. Note that in 1D, all information about the superconductor is simply included in the strength of the on-site  $s$ -wave gap  $\Delta_0$  and the hopping term describes coupling between the impurities on superconducting sites only (as opposed to the superconductor bandwidth in BdG model above, see<sup>39</sup> section 2). Fig. 3 shows that a 1D model qualitatively gives similar results the 2D model. Importantly, the hopping term, which can be tuned experimentally by placing atoms at different distances, may also drive quantum phase transition from the trivial phase (Pf>0) to the topological phase (Pf<0) with MFs at the ends. A one-dimensional version of this Hamiltonian is also considered in Ref.<sup>12</sup> in the context of MFs in disordered magnetic islands on a superconductor.

A key advantage of the 1D model is that it lends itself to an analytical solution, which shows that for a given angle  $\theta$  between adjacent moments, the Pfaffian for the system is negative when

$$\begin{aligned} \sqrt{\Delta_0^2 + (|\mu| + 2|t \cos(\theta/2)|)^2} &> |B|, \\ |B| &> \sqrt{\Delta_0^2 + (|\mu| - 2|t \cos(\theta/2)|)^2} \end{aligned} \quad (2)$$

(see<sup>39</sup>, section 3 for the derivation). The negative value of the Pfaffian is a necessary condition for this system to be in a topological phase; however, it not sufficient, as the bulk of atomic chain remains must also be gapped. For example,  $\theta = 0, \pi$  have the widest range of negative Pfaffian in Eq. 2; unfortunately, this full range is gapped. The min-gap for low energy excitation is related to

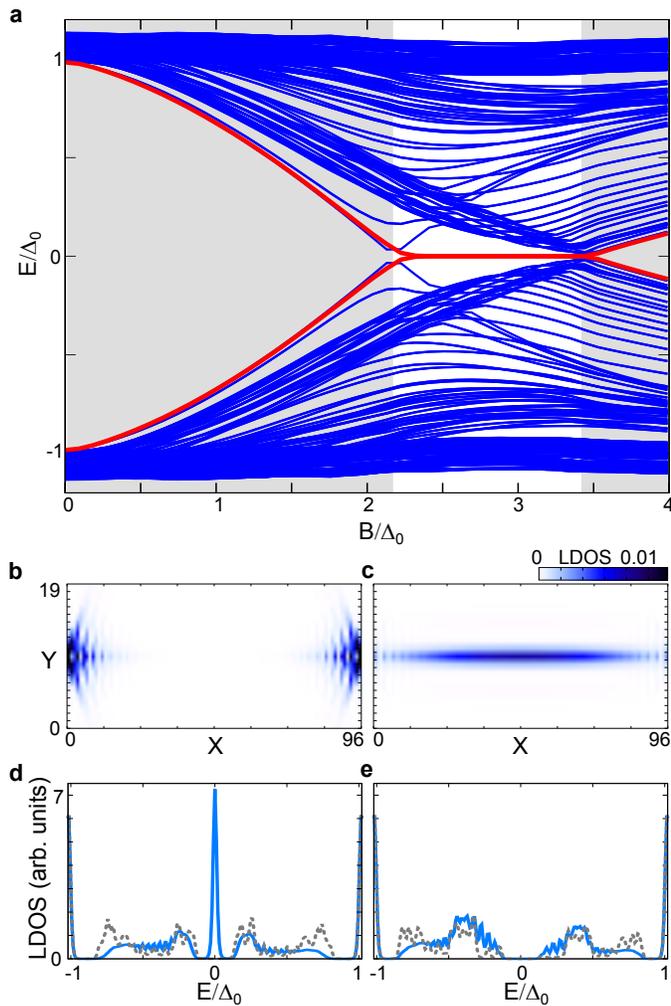

FIGURE 2. (a) Calculated energy spectrum, marked by blue lines, for 96 classical spins placed in the middle of the  $N_a \times N_b = 96 \times 19$  grid using periodic BC. Parameters for the plot are :  $\mu/\Delta_0 = 2.12$ ,  $t/\Delta_0 = 2.34$ ,  $V/\Delta_0 = 2.81$  and  $T/\Delta_0 = 0.01$ . The regions corresponding to the trivial phase ( $\text{Pf} > 0$ ) are shaded gray. Red thick line represents the lowest energy excitation using open BC. (b,c) The spatial distribution of the local density of states corresponding to the lowest excitation state in the non-trivial ( $B/\Delta_0 = 2.87$ ,  $\text{Pf} < 0$ ) and the trivial ( $B/\Delta_0 = 2.23$ ,  $\text{Pf} > 0$ ) phase. Lattice coordinates  $X$  and  $Y$  correspond to the  $N_a$  direction (along the chain) and  $N_b$  direction (orthogonal to the chain) respectively. (d,e) Local density of states at the chain ends (blue solid line) and in the middle of the chain (gray dashed line) as a function of energy for non-trivial and trivial phase taking into account first 96 energy eigenvalues. The intrinsic line-width of the energy eigenstates is taken to be  $\omega/\Delta_0 = 1 \times 10^{-3}$  for this plot.

strength of the  $p$ -wave pairing that emerges on the chain because of the combination of hopping, pairing, and local Zeeman terms in the Hamiltonian. Calculations of the spectra in both 2D and 1D model described above reveal the energy scale, which separates the zero energy MF states (localized at the two ends) from the next available excitation of the system. In a certain limit, the 1D

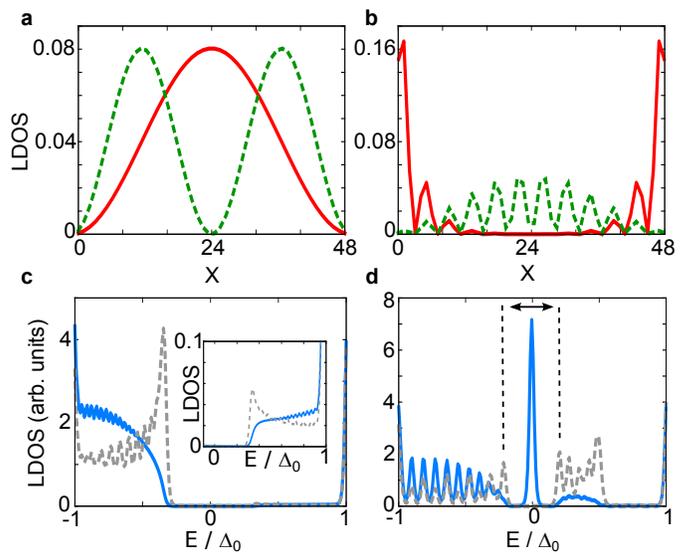

FIGURE 3. (a,b) The spatial profile of the two lowest excitation states of magnetic chain containing 48 atoms for  $\mu/\Delta_0 = 4$ ,  $B/\Delta_0 = 5$ ,  $\theta = \pi/2$  (marked by red solid and green dashed line respectively). Tuning the hopping term  $t$  drives quantum phase transition from the trivial ( $t/\Delta_0 = 0.4$ ,  $\text{Pf} > 0$ ) (a) to the topological ( $t/\Delta_0 = 1$ ,  $\text{Pf} < 0$ ) phase (b). (c,d) Local density of states calculated for the same parameters as in (a) and (b) at the chain ends (blue solid line) and in the middle of the chain (gray dashed line). Note that for this choice of parameters spectrum in (c) is asymmetric in energy (see inset). Importantly, in (d) the two MF states around zero energy are separated by the effective mini gap  $\Delta_p$  from the other states in the spectrum (marked by double arrow line).

model can be directly mapped<sup>12</sup> to the original proposal by Kitaev for realization of MF end mode, which is a superconducting wire with nearest neighbor pairing<sup>1</sup>, but general eigenvalues can be obtained even without this mapping, see<sup>39</sup> section 2. The value of this mini-gap depends on the relative values of  $\mu$ ,  $t$ ,  $B$ , and angle  $\theta$  (see Fig 4).

A non-collinear arrangement of magnetic moments in a chain is essential to realize robust MF end modes. When transformed to a basis parallel to the spiraling on-site magnetic field, the hopping becomes spin-dependent giving rise to spin-orbit coupling and hence to the usual mechanisms for MF end modes. Without detailed modeling of the surface magnetism it is difficult to predict whether specific magnetic atomic chains would have a spiral spin-arrangement. We suggest that exploring the full freedom of the linear chain geometry may provide a feasible approach to create favorable conditions for non-collinear magnetic moments of adjacent atoms. For example, double or zig-zag chain structures with antiferromagnetic interactions are likely to become frustrated and result in spiral orientation of magnetic moments in the chain<sup>37</sup>. To explore some of these possible geometries (Fig. 5a), we map these chains into equivalent linear chains with the nearest  $t_1$  and the next nearest  $t_2$  hop-

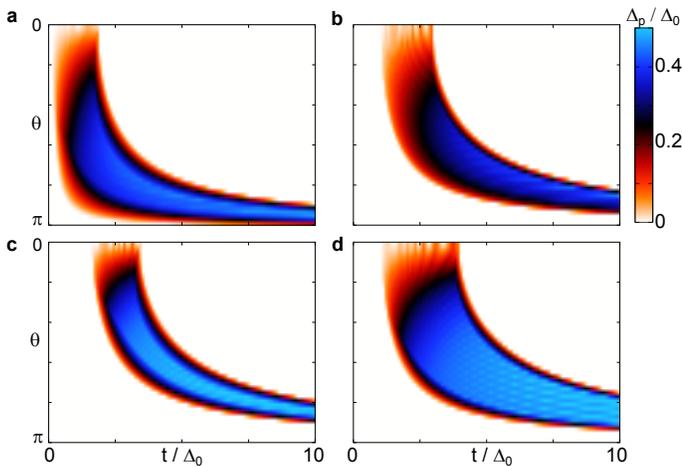

FIGURE 4. The value of the mini gap as a function of tunnel coupling and angle  $\theta$  calculated for the 1D model : (a)  $\mu/\Delta_0 = 2$  and  $B/\Delta_0 = 3$ ; (b)  $\mu/\Delta_0 = 2$  and  $B/\Delta_0 = 5$ ; (c)  $\mu/\Delta_0 = 5$  and  $B/\Delta_0 = 2$ ; (d)  $\mu/\Delta_0 = 5$  and  $B/\Delta_0 = 4$ .

ping as shown in Fig. 5b. In the simplest case for which  $\theta$  is assumed constant, we show that these chains can also support topological phase when

$$\sqrt{\Delta_0^2 + (\mu + 2 \cos(\theta/2)t_1 - 2 \cos(\theta)t_2)^2} > |B|, \\ |B| > \sqrt{\Delta_0^2 + (\mu - 2 \cos(\theta/2)t_1 - 2 \cos(\theta)t_2)^2} \quad (3)$$

(see<sup>39</sup> section 3a for further details). We note again that these chains may provide easy-to-fabricate structures that would ensure non-collinear spin arrangements required for realization of MF end modes.

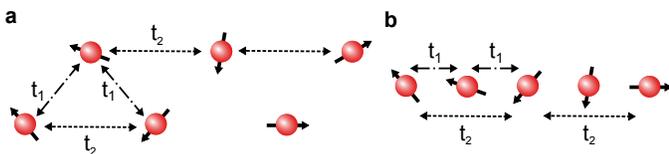

FIGURE 5. (a) Array of magnetic atoms arranged in two rows (zig-zag chain). The coupling among neighboring atoms corresponding to different rows is  $t_1$  and the coupling between atoms within the same row is  $t_2$ . (b) Equivalent magnetic moment configuration represented as a single chain with the next nearest coupling.

Lastly, we comment on the experimental feasibility of the proposed approach. As shown here the strength of the mini-gap associated with the  $p$ -wave pairing can sometimes exceed 30-40% of the gap of the host superconductor (Fig. 4). Nevertheless, using an  $s$ -wave superconductor with large gap  $\Delta_0$  (and measuring at the lowest temperatures) would increase the chance of experimental success. Other factors such as size of the magnetic moment  $B$  or hopping matrix element  $t$  are also important and can be optimized experimentally using magnetic atoms with different spin or building chains with different spacing. A systematic experimental approach can start by characterizing the single-impurity states and their modification when impurities are brought close enough to interact<sup>33</sup>. These measurements could be used to map effective 1D model parameters (effective hopping, chemical potential and exchange coupling) and allow investigation of the finite size effects on the excitation spectrum. A different approach would be to start from magnetic chains grown using self-assembled techniques. Note that self-assembled chains consisting of  $\sim 50$  atoms with spiral arrangement of magnetic moments are already reported<sup>37</sup>. Such chains would be an ideal starting point to investigate interaction between Majorana fermions. For example, examining coupled chains can provide direct experimental means to demonstrate the  $Z_2$  character of the MF end modes by showing that they appear only in odd number of coupled chains. Finally, as structures of different shapes are equally easy to assemble in STM, one can envision viable route towards braiding experiments in arrays of coupled chains in a similar fashion as proposed for semiconductor nanowire structures<sup>43-45</sup>.
