## Abstract

Valence and spin states of Fe were investigated in a glass of almandine ($Fe_3Al_2Si_3O_{12}$) composition to 91 GPa by X-ray emission spectroscopy and energy- and time-domain synchrotron Mössbauer spectroscopy in the diamond anvil cell. Changes in optical properties, total spin moment and Mössbauer parameters all occur predominantly between 1 bar and ~30 GPa. Over this pressure range, the glass changes from translucent brown to opaque and black. The total spin moment of the glass derived from X-ray emission spectroscopy decreases by ~20%. The two Mössbauer spectroscopy approaches reveal consistent changes in sites corresponding to 80-90% $Fe^{2+}$ and 10-20% $Fe^{3+}$. The high-spin $Fe^{2+}$ doublet exhibits a continuous decrease in isomer shift and increase in line width and asymmetry. A high-spin $Fe^{3+}$

1

31    doublet with quadrupole splitting of ~1.2 mm/s is replaced by a doublet with quadrupole splitting

32    of ~1.9 mm/s, a value higher than all previous measurements of high-spin $Fe^{3+}$ and consistent

33    with low-spin $Fe^{3+}$. These observations suggest that $Fe^{3+}$ in the glass undergoes a gradual

34    transition from high to low spin state between 1 bar and ~30 GPa. Almandine glass is not

35    expected to undergo any abrupt transitions in electronic state at deep mantle pressures.

36    Keywords: silicate glass; spin transitions; Mössbauer spectroscopy; nuclear forward

37    scattering; X-ray emission spectroscopy

## 1. Introduction

39    The high-pressure behavior of Fe-rich silicate liquids is key to the differentiation of the

40    mantle from a primordial magma ocean (Labrosse et al. 2007; Stixrude et al. 2009; Lee et al.

41    2010) and to understanding observations of possible dense melt-rich regions near the core-mantle

42    boundary (Williams and Garnero 1996). The dynamics of melt in the deep mantle is largely

43    controlled by the behavior of Fe, Earth's densest major elemental component. A density

44    crossover in the deep mantle, with negatively-buoyant Fe-rich silicate melt relative to solid

45    mantle silicates, has been suggested based on the compressibility of melt (Stixrude et al. 2009;

46    Thomas et al. 2012; Muñoz Ramo and Stixrude 2014) and partitioning of Fe into the liquid phase

47    (Nomura et al. 2011; Andrault et al. 2012). However, detailed characterization of mantle melt is

48    challenging due both to experimental difficulty of stable melting at mantle pressures and limited

49    capability to probe liquid structures at extreme conditions. As low-temperature analogues to

50    melts, silicate glasses have been explored in recent high-pressure experiments (e.g. Nomura et al.

51    2011) and computational studies (e.g. Stixrude and Karki 2005). In both silicate liquids and

52  glasses a range of coordination environments may evolve continuously with composition and

53  pressure (Stixrude and Karki 2005), but a surprising sharp transition was recently reported at ~70

54  GPa in Fe-bearing melt and glass and attributed to a spin transition (Nomura et al. 2011).

55      Spin transitions in crystalline mantle phases and their implications for seismic properties

56  and chemical partitioning have been the focus of much recent study, particularly of ferropericlase

57  (Badro et al. 2003) and silicate perovskite (Badro et al. 2004). In ferropericlase, a spin transition

58  occurs in 6-fold-coordinated $Fe^{2+}$ at pressures between 50 and 90 GPa, depending on Fe content

59  (Speziale et al. 2005; Fei et al. 2007). In silicate perovskite (now known as bridgmanite), the

60  presence of multiple sites and valence states makes characterizing the spin state more complex,

61  but both experiments and density functional theory results indicate that a spin transition occurs in

62  6-fold-coordinated $Fe^{3+}$ at 15-50 GPa (Catalli et al. 2010; Hsu et al. 2011; Lin et al. 2012). At

63  high temperatures relevant to Earth's mantle, the effects of Boltzmann statistics and kinetics have

64  been predicted (Sturhahn et al. 2005; Tsuchiya et al. 2006; Lin and Tsuchiya 2008) and observed

65  (Lin et al. 2007; Kantor et al. 2009) to broaden each of these spin transitions to occur over a

66  pressure interval extending for ~30-50 GPa.

67      Liquids and glasses are characterized by continuous structural evolution under

68  compression that may also contribute to the pressure-broadening of spin transitions. At mantle

69  temperatures, the spin transition in liquid $Fe_2SiO_4$ has been predicted to take place over a >200

70  GPa pressure range (Muñoz Ramo and Stixrude 2014). While this transition might affect the

71  depth of a solid-liquid density crossover in the mantle, it would not be observable as a

72  discontinuity. In contrast, Nomura et al. (2011) reported a sharp change in Fe partitioning in

73  partially-melted $(Mg_{0.89}Fe_{0.11})_2SiO_4$ between 73 and 76 GPa. At similar pressures, between 59

74    and 77 GPa, they also observed that X-ray emission spectra of $(Mg_{0.95}Fe_{0.05})SiO_3$ glass indicated

75    a complete spin transition. Other studies are not consistent with abrupt spin transitions in liquids

76    and melts. No sharp change in partitioning was observed in chondritic melt at pressures up to 120

77    GPa (Andrault et al. 2012). Studies of several different Fe-bearing silicate glass compositions—

78    10-50% $FeSiO_3$, $Fe^{3+}/\Sigma Fe$ from 0-78%, with and without Al—showed either no change in spin

79    state (Mao et al. 2014; Prescher et al. 2014) or a gradual, partial change (Gu et al. 2012;

80    Murakami et al. 2014) at high pressures. Gradual increases in cation coordination rather than spin

81    transitions were inferred to be primarily responsible for pressure-induced changes in these glasses

82    (Mao et al. 2014; Prescher et al. 2014).

83    Studies of Fe spin state at extreme pressures rely on two complementary synchrotron

84    techniques: X-ray emission spectroscopy and Mössbauer spectroscopy. X-ray emission

85    spectroscopy (XES) measures energies of electron exchange between $3p$ and $3d$ orbitals, which

86    depend on bonding, coordination, valence and spin states (Peng et al. 1994; Rueff et al. 1999;

87    Mattila et al. 2007). This technique was the first used to identify pressure-induced spin transitions

88    in major lower mantle phases (Badro et al. 2003, 2004). However, XES only provides a

89    constraint on the total spin moment of the bulk material, not of individual states or sites.

90    Mössbauer spectroscopy provides a complementary constraint on coordination, site occupancy,

91    valence, and spin states of Fe via the energies of recoil-free nuclear resonance in solid materials.

92    The technique can be applied to glasses but not silicate liquids; for insights on melt structures, a

93    wide variety of silicate glass compositions have been examined at ambient pressure by

94    Mössbauer spectroscopy (MS) with a conventional radioactive source (e.g. Mao et al. 1973;

95    Virgo and Mysen 1985; Jayasuriya et al. 2004; Dunlap and McGraw 2007; Rossano et al. 2007;

96    Cottrell and Kelley 2011). [57]Fe nuclei of each site, species and spin state resonate at energies with

97    isomer shift (IS), quadrupole splitting (QS) and hyperfine splitting that reflect the local electric

98    and magnetic fields. The relative intensities of each site indicate the abundance of $Fe^{2+}$ and $Fe^{3+}$

99    in each spin state and coordination environment. For Mössbauer spectroscopy of materials at high

100   pressures, synchrotron radiation can provide a more brilliant, highly-focused source. Energy-

101   domain synchrotron Mössbauer spectroscopy (E-SMS) is identical to MS with the exception of a

102   more brilliant source obtained by monochromatizing a synchrotron beam to ~neV linewidth

103   (Smirnov et al. 1997; Mitsui et al. 2009; Potapkin et al. 2012). Mössbauer parameters IS and QS

104   can also be derived from nuclear forward scattering (also known as time-domain synchrotron

105   Mössbauer spectroscopy, T-SMS), in which nuclear resonance is observed in ~few hundred

106   nanosecond time windows between pulses of synchrotron radiation   (Jackson et al. 2005;

107   Sturhahn et al. 2005). The combination of XES, E-SMS and T-SMS techniques offers the best

108   approach for separation of competing effects and thus understanding complex Fe-bearing

109   materials such as silicates at lower mantle conditions.

110          Fe,Al-bearing silicate glass compositions examined in previous studies are rich in ferric

111   iron; glass of almandine garnet composition provides a useful contrast as it is rich in both

112   aluminum and ferrous iron. Almandine is also of particular interest among silicate minerals for its

113   unusual electronic structure, with high quadrupole splitting at ambient conditions and at high

114   pressures (Dyar et al. 2006; Mao et al. 2013). At ~80 GPa and 2500 K, almandine end-member

115   $Fe_3Al_2Si_3O_{12}$ has been observed to transform to a single-phase orthorhombic perovskite

116   consistent with stoichiometry $(Fe_{0.75}Al_{0.25})(Al_{0.25}Si_{0.75})O_3$ (Dorfman et al. 2012). Structural

5

117    refinement of X-ray diffraction data for this phase shows that nearly all Fe resides in the larger A-

118    site and there are no discontinuities in its equation of state up to 150 GPa.

119        In this work, we apply multiple techniques to characterize the pressure-dependence of

120    valence and spin states in almandine glass at pressures up to 91 GPa. Total spin moment is

121    determined by XES. Valence, spin, and coordination states are constrained by E-SMS and T-

122    SMS.

## 2. Material and methods

124        $^{57}$Fe-enriched almandine glass was prepared from a stoichiometric mixture of $^{57}$Fe$_2$O$_3$

125    (Cambridge Isotope Laboratories, Inc., $^{57}$Fe 94.3%), Al$_2$O$_3$ (Alfa Aesar 99.9%) and SiO$_2$

126    (Johnson Matthey, 99.995%) after the method described by Geiger et al. (1987). Approximately

127    300 mg of reagents were placed in a covered graphite crucible and heated from 1000°C to

128    1200°C at a rate of 4°C/min. The sample was held at 1200°C for 6 minutes before being

129    quenched in air. To ensure a homogeneous product the resultant material was subsequently arc

130    melted under an argon atmosphere. The composition and homogeneity of the glass were

131    confirmed by microprobe analysis (Supplementary Table 1). The normalized formula,

132    Fe$_{2.69}$Al$_{2.14}$Si$_{2.93}$O$_{12}$, is slightly depleted in Fe and enriched in Al relative to pure almandine.

133        The valence state of Fe in the starting material was determined by Mössbauer

134    spectroscopy. MS was performed over ~1 day with a $^{57}$Co radioactive source at the Advanced

135    Photon Source (APS) sector 3 offline Mössbauer laboratory. The spectrum was fit to a two-site

136    model (Figure 1, Table 1) using MossA software (Prescher et al. 2012). The dominant site, 82(3)

137    percent of the iron, has QS of 2.08(3) mm/s and IS relative to an iron standard of 0.982(14)

138 mm/s. These parameters are typical of $Fe^{2+}$ in silicates (Dyar et al. 2006) and glasses (Dyar 1985;

139 Virgo and Mysen 1985; Burkhard 2000; Jayasuriya et al. 2004; Mysen 2006; Rossano et al. 2007;

140 Gu et al. 2012; Mao et al. 2014; Murakami et al. 2014; Prescher et al. 2014). The QS of $Fe^{2+}$ in

141 almandine glass is considerably lower than the 3.53 mm/s observed in crystalline almandine

142 (Woodland and Ross 1994; Dyar et al. 2006). A significant minority site was observed with

143 QS=1.23(11) mm/s and IS=0.39(5) mm/s, consistent with $Fe^{3+}$ in silicate glasses but with higher

144 QS than $Fe^{3+}$ in silicate garnets. This analysis yields $Fe^{3+}/\Sigma Fe$ of 18(3)%.

145　　　　High-pressure experiments were performed using symmetric diamond anvil cells (DAC).

146 Glass samples were loaded with a ~8 μm ruby ball in NaCl, cryogenically-cooled Ar or

147 pressurized Ne (Rivers et al. 2008) (Figure 2). A 50 to 80-μm diameter hole was drilled through a

148 Re or Be gasket to serve as a sample chamber. Diamond anvils with 150, 200 and 300-μm culet

149 size were used in separate experiments to reach maximum pressures of 91, 86, and 66 GPa,

150 respectively. Pressure was calibrated by ruby fluorescence (Mao et al. 1986) or Raman

151 spectroscopy of the tip of the diamond anvil (Akahama and Kawamura 2006).

152　　　　XES was performed at pressures up to 66 GPa at beamline GALAXIES of Synchrotron

153 SOLEIL (Rueff et al. 2015). At GALAXIES, the beam size was 30x80 microns, incident energy

154 was 10 keV and typical count rates were 70-150 counts/s. The emission signal was maximized by

155 directing incident radiation through the diamond and collecting spectra at an angle of

156 approximately 10° minimizing the path through the beryllium gasket.

157　　　　T-SMS experiments were conducted at pressures up to 85 GPa using beamline 16-ID-D of

158 the APS. Kirkpatrick-Baez mirrors were used to focus the X-ray beam to 30x40 μm. The storage

159   ring was operated in standard-mode with 24 bunches separated by 153 ns. Data were collected

160   between 14 and 130 ns after excitation. Measurements were taken both with and without a 0.5-

161   μm thick $^{57}$Fe-enriched stainless steel foil as a reference. Sample count rates at high pressure

162   were 30-150 counts/s and spectra were typically collected for 30-60 minutes. At ambient

163   pressure, both T-SMS and MS give consistent results (Figure 1, Tables 1-2).

164       E-SMS experiments were conducted at pressures up to 91 GPa at beamline ID18 of the

165   European Synchrotron Radiation Facility (ESRF) (Rüffer and Chumakov 1996; Potapkin et al.

166   2012). The synchrotron beam was focused to 9x14 μm and monochromatized to a bandwidth of

167   ~5.5 neV at the $^{57}$Fe resonant energy by a $^{57}$FeBO$_3$ single crystal. The crystal monochromator

168   was oscillated in a sinusoidal mode over +/- 5 mm/s to provide a range of energies for absorption

169   measurements via the Doppler effect. Source velocity was calibrated with an α-Fe foil. The

170   linewidth and center shift of the source were verified before and after each measurement with

171   K$_2$Mg$^{57}$Fe(CN)$_6$ standard.

## 3. Results

173       Glass samples were compressed without heating to maximum pressures up to 91 GPa. At

174   ambient conditions, the glass is honey-brown and translucent, but darkens with pressure,

175   becoming black and opaque by 34 GPa (Figure 2). Pressure-induced color change of

176   (Mg$_{0.8}$Fe$_{0.2}$)SiO$_3$ enstatite-composition glass was determined by optical absorption spectroscopy

177   to occur from ~15-50 GPa (Murakami et al. 2014). An analogous color-change in crystalline

178   samples is known to be associated with the garnet-perovskite transition (O'Neill and Jeanloz

179   1994; Kesson et al. 1995; Dorfman et al. 2012) but is not observed in cold-compressed almandine

180   to pressures above 1 Mbar (Dorfman et al. 2012). This change in optical properties decreases

181   radiative thermal conductivity of Fe-bearing silicates in the mantle and may be associated with

182   changes in electronic configuration (Murakami et al. 2014).

### 3.  1. X-ray emission spectroscopy

184   The observed Fe Kβ X-ray emission spectrum at ambient conditions is composed of a

185   main $K\beta_{1,3}$ peak and a well-resolved lower-energy satellite Kβ' peak and is consistent with iron

186   entirely in the high spin state (Figure 3). Up to 66 GPa in almandine glass, the Kβ' peak intensity

187   continuously decreases and breadth increases (Figure 3). These changes may be due to either a

188   gradual spin-pairing transition or pressure-induced broadening effects (Gu et al. 2012; Mao et al.

189   2014; Murakami et al. 2014).

190   Distinguishing between a gradual spin transition and spectral broadening depends on

191   quantitative comparison with reference spectra. Several methods have been proposed for

192   quantifying spin crossovers (Kantor et al. 2006; Vankó et al. 2006; Mao et al. 2014) and each

193   may result in a different interpretation of the data. Simple peak-fitting techniques do not

194   adequately model the Kβ spectrum due to the complexity of the energy multiplets from which the

195   broader features are composed (Vankó et al. 2006). Instead, the spin state is derived from an

196   integrated difference between spectra and reference high- and low-spin standard spectra.

197   Relevant standards are keys to this method. Spectral differences can be due to differences in

198   instrument resolution, crystallographic environment, and stress conditions as well as spin state, so

199   these confounding factors must be minimized between standards and experiments (De Groot

200   2001; Vankó et al. 2006; Mao et al. 2014). A modification of the integrated difference technique

201    was recently proposed to minimize the effects of pressure-induced broadening (Mao et al. 2014).

202    Difference spectra are summed such that negative differences at Kβ' are offset by positive

203    differences in the shoulder between Kβ' and $K\beta_{1,3}$. This integrated relative difference (IRD)

204    method was suggested to better model pressure-induced spin transitions both in (Mg,Fe)O

205    ferropericlase and in Fe-bearing silicate glass (Mao et al. 2014).

206          The IRD analysis was applied to the almandine glass XES using as references (Mg,Fe)O

207    from Lin et al. (2010) and the ambient-pressure glass spectrum. No significant difference is

208    observed between the glass at 1 bar and (Mg,Fe)O at 1 bar. IRD at high pressure relative to either

209    high-spin standard is identical within symbol size. Between 1 bar and the first high-pressure

210    measurement at 9 GPa, a decrease in total spin moment begins. Total spin moment decreases

211    gradually to ~80% of the high-spin standard by 27 GPa (Figure 3). At higher pressures up to 66

212    GPa there is no significant further change in spin. The gradual change in the spectrum above 27

213    GPa reflects only broadening due to pressure and/or differential stress.

214          In previous work on silicate glass at high pressure, analysis by the integrated absolute

215    difference (IAD) method of Vankó et al. (2006) showed a gradual spin transition (Gu et al. 2012)

216    while the IRD method showed only broadening (Mao et al. 2014). Analysis of our spectra with

217    the IAD method also produces an apparent gradual loss of spin moment over the entire pressure

218    range (Supplementary Figure 1). We thus confirm that the IRD analysis removes pressure-

219    induced broadening and reduces the apparent change in spin relative to the IAD analysis, but we

220    still observe partial loss of spin moment. The spin change can be linked to a valence state and site

221    using Mössbauer spectroscopy.

## 3. 2. Synchrotron Mössbauer spectroscopy

Synchrotron Mössbauer spectroscopy was performed on almandine glass at high pressures in both energy- and time-domain modes. E-SMS (Figure 4) and T-SMS spectra (Supplementary Figure 2) evolve continuously with pressure. The major feature in E-SMS spectra is the asymmetrical doublet identified as $Fe^{2+}$. With compression the $Fe^{2+}$ doublet broadens and becomes increasingly asymmetrical. Pressure-induced changes in the $Fe^{2+}$ doublet are consistent with previous E-SMS measurements of $Fe^{2+}$-rich glasses with compositions $(Mg_{0.8}Fe_{0.2})SiO_3$ and $(Mg_{0.823}Fe_{0.135})(Al_{0.057}Si_{0.982})O_3$ (Murakami et al. 2014; Prescher et al. 2014). The small shoulder observed between the $Fe^{2+}$ lines (Figure 4) is identified as one leg of the $Fe^{3+}$ doublet. At higher pressures, a shoulder appears at higher velocity on the $Fe^{2+}$ doublet.

T-SMS spectra (Supplementary Figure 2) at low pressure have a sharp beat at ~60 ns and a broad decay after ~100 ns. At higher pressures, the beat shifts with pressure to faster times and becomes less distinct. Above 26 GPa, another small beat appears at ~80 ns. Despite differences in $Fe^{3+}/\Sigma Fe$ and total iron content, qualitatively similar spectra were observed at high pressure in $(Mg_{0.80}Fe_{0.20})SiO_3$ (~10% $Fe^{3+}$) and $(Mg_{0.75}Fe_{0.20}Al_{0.10}Si_{0.95})O_3$ (~35% $Fe^{3+}$) glasses by Gu et al. (2012) and $(Mg_{0.79}Fe_{0.10}Al_{0.10}Si_{0.96})O_3$ (78% $Fe^{3+}$) glass by Mao et al. (2014). However, starting from 17 GPa and increasing with pressure in the almandine glass studied here, resonant intensity is observed at ~110 ns. Neither previous study reports this structure, either due to difference in electronic states or effective sample thickness.

Modeling Mössbauer spectra of glasses is challenging due to the range of coordination environments and site geometries in a disordered structure. A simple two-site model with a distribution over IS or QS cannot fit the asymmetry observed in E-SMS and the complex

11

244   structure in T-SMS. An asymmetrical $Fe^{2+}$ doublet is observed in silicate glasses due to a range

245   of coordination environments (Mao et al. 1973; Alberto et al. 1996). For glasses at both ambient

246   conditions (Alberto et al. 1996; Lagarec and Rancourt 1997) and high pressures (Prescher et al.

247   2014), a correlated distribution over both IS and QS fits the asymmetrical $Fe^{2+}$ doublet

248   (Supplementary Figure 3). E-SMS data in this study were analyzed using the correlated

249   distribution model of Lagarec and Rancourt (1997) implemented for fitting E-SMS spectra in

250   MossA software (Prescher et al. 2012). The correlated distribution for $Fe^{2+}$ can also be modeled

251   with a pair of doublets of approximately equal intensity, one representing low-IS, low-QS and the

252   other high-IS, high-QS (Supplementary Figure 3) (Virgo and Mysen 1985; Jayasuriya et al.

253   2004). T-SMS data in this study were analyzed using a paired $Fe^{2+}$ doublet model with fixed

254   weighting in the CONUSS software package (Sturhahn 2000). T-SMS fits with a pair of doublets

255   for $Fe^{2+}$ are consistent with observed E-SMS spectra (Supplementary Figure 2). $Fe^{3+}$ doublets are

256   not fully resolved but assumed to be symmetric as previously observed at ambient pressure

257   (Virgo and Mysen 1985) and high pressure (Prescher et al. 2014).

258       Our results demonstrate consistent pressure-dependence of Mössbauer parameters in three

259   separate compression experiments with two SMS techniques (Figure 5, Tables 1-2). Observed

260   Mössbauer parameters for the $Fe^{2+}$ doublet(s) at all conditions studied are consistent with

261   previous observations of high-spin $Fe^{2+}$ in glasses (Dyar 1985; Virgo and Mysen 1985; Burkhard

262   2000), with average QS of 2.0-2.3 mm/s and IS of 0.8-1.1 mm/s. The QS of high-spin $Fe^{2+}$

263   increases slightly from 1 bar to 30 GPa and then slightly decreases up to the maximum pressure

264   of 91 GPa. The IS of high-spin $Fe^{2+}$ decreases with pressure. The most significant change in the

265   $Fe^{2+}$ component is an increase in the correlated broadening parameter related to the covariance of

266     QS and IS, $\rho$, particularly between 1 bar and ~40 GPa. In T-SMS fits, the increase in correlated

267     broadening is modeled as a divergence of both QS and IS of two high-spin $Fe^{2+}$ doublets. The

268     weight of the high-spin $Fe^{2+}$ component does not change significantly. If the change in spin state

269     indicated by XES corresponds to a high-to-low spin transition in $Fe^{2+}$, we would expect a

270     decrease in QS of the $Fe^{2+}$ site, as for the high-to-low spin transition in $Fe^{2+}$ in bridgmanite (Hsu

271     et al. 2010), but this is not observed. Our data also do not support pressure-induced growth of an

272     intermediate spin $Fe^{2+}$ component with parameters as reported by Murakami et al. (2014). The

273     broadening of the $Fe^{2+}$ doublet could be interpreted as a gradual transition of half of the $Fe^{2+}$

274     component to intermediate spin below ~40 GPa. This is consistent with the total spin moment

275     measured by XES, but unlikely as there is no obvious reason why the spin transition would stop,

276     incomplete, at ~40 GPa.

277         Observations of the $Fe^{3+}$ component(s) are consistent with a high-to-low spin transition.

278     At pressures >30 GPa, the values of QS for the $Fe^{3+}$ site are 1.7-2.0 mm/s. These values are

279     outside the range of previous observations for high-spin $Fe^{3+}$ at ambient conditions (Figures 5-6)

280     (Dyar 1985; Virgo and Mysen 1985; Burkhard 2000) and similar to previous observations of low-

281     spin $Fe^{3+}$-bearing compounds (Greenwood and Gibb 1971; Pasternak et al. 2002). Moreover, both

282     the weight of the $Fe^{3+}$ component, ~20% of the total Fe, and the pressure at which the

283     $Fe^{3+}$ shoulder completes its shift, ~30 GPa, match the decrease in spin moment observed in XES

284     data (Figure 3). A high-to-low spin transition in $Fe^{3+}$ should be observed as a decrease in the

285     intensity of the high-spin doublet and corresponding growth of the low-spin doublet with lower

286     IS and higher QS (Pasternak et al. 2002). We have thus chosen a model with two $Fe^{3+}$ doublets,

287     although these two doublets are not fully resolved in our MS data. We are also unable to resolve

13

288    the minimum pressure at which the low-spin $Fe^{3+}$ appears, but at 15 GPa ~30% of the $Fe^{3+}$ is in

289    the low-spin state. The high- and low-spin doublets coexist over a wider pressure range in the

290    glass sample loaded in NaCl vs. Ne medium. This suggests that differential stress may result in a

291    broader spin transition, as reported in (Mg,Fe)O (Lin et al. 2009).

292          Previous Mössbauer studies of silicate glasses found generally similar QS and IS values

293    and changes with pressure as in our study (Figure 6). QS and IS for all sites in the almandine

294    glass are similar to those constrained by previous E-SMS studies on Fe-bearing silicate glasses at

295    high pressures (Murakami et al. 2014; Prescher et al. 2014). Studies using both E-SMS and T-

296    SMS techniques on a wide range of compositions have found an increase in QS of $Fe^{2+}$ at

297    pressures up to 20-40 GPa (Gu et al. 2012; Mao et al. 2014; Murakami et al. 2014; Prescher et al.

298    2014). A similar QS of high-pressure $Fe^{3+}$ was observed in $Fe^{3+}$-rich glass studied by Prescher et

299    al. (2014) and Gu et al. (2012), but not by Mao et al. (2014). IS of $Fe^{2+}$ was observed to decrease

300    with pressure in both previous E-SMS studies (Murakami et al. 2014; Prescher et al. 2014).

301    However, previous studies have offered different interpretations of these observations: no spin

302    transition (Mao et al. 2014; Prescher et al. 2014), a gradual high-to-low spin transition in

303    $Fe^{3+}$ (Gu et al. 2012) or a high-to-intermediate spin transition in $Fe^{2+}$ (Murakami et al. 2014). In

304    addition to differences in composition between these studies, differences in interpretation of

305    Mössbauer parameters are due to details of E-SMS and T-SMS fitting and availability and

306    interpretation of XES data.

307    **4. Discussion**

308    The multiple techniques used in this study enable us to provide a strong constraint on the

309    pressure-dependence of spin states of Fe in almandine glass. Optical properties, XES, and

310    Mössbauer parameters of $Fe^{3+}$ all exhibit changes between 1 bar and ~30 GPa. These results

311    support a gradual, complete transition of $Fe^{3+}$ in almandine glass from high to low spin and no

312    detectable change in spin state of $Fe^{2+}$.

313    This transition in $Fe^{3+}$ could not be reliably identified in previous studies that did not use

314    multiple experimental techniques. Fitting T-SMS spectra alone suffers from non-unique

315    constraints on Mössbauer parameters. Gu et al. (2012) model spectra using a pair of $Fe^{2+}$ doublets

316    similar to those in this study, but their strong change in intensity with pressure is inconsistent

317    with other studies of silicate glasses and may be an artifact of non-unique fitting. Mao et al.

318    (2014) restrict their model to two sites of constant intensity, one each for high spin $Fe^{2+}$ and $Fe^{3+}$,

319    but their modeled energy-domain spectra exhibit varying degrees of asymmetry which is not

320    explained. The previous E-SMS study of $Fe^{3+}$-rich silicate glass (Prescher et al. 2014) finds a

321    similar increase in QS as in our observations of almandine glass (Figure 6). The doublet

322    identified at pressures above 20 GPa as intermediate spin $Fe^{2+}$ by Murakami et al. (2014) is

323    consistent with $Fe^{3+}$ at high pressures in this study and Prescher et al. (2014) (Figure 6).

324    However, previous studies using the E-SMS technique were not combined with XES

325    measurements and thus were unable to relate changes in Mössbauer parameters to changes in

326    total spin moment.

327    While our results and previous studies cover a wide range of compositions, all time- or

328    energy-domain Mössbauer studies of glass to date consistently find that there is no sharp

329    transition in spin or structure with pressure up to 126 GPa (Gu et al. 2012; Mao et al. 2014;

330  Murakami et al. 2014; Prescher et al. 2014). Almandine glass is much richer in Fe than the

331  compositions studied in other work; this may promote a spin transition at relatively lower

332  pressures (Prescher et al. 2014). The sharp spin transition observed in XES data by Nomura et al.

333  (2011) in $(Mg_{0.95}Fe_{0.05})SiO_3$ glass at 76 GPa is inconsistent with this and other studies. Similar

334  experimental methods were used by Nomura et al. (2011) and more recent studies, and thus these

335  results remain unexplained and unreplicated.

336       A spin transition in $Fe^{3+}$ in silicate glasses is analogous to transitions in crystalline Fe-

337  bearing silicates. In bridgmanite, $Fe^{3+}$ in the 6-fold-coordinated B-site is predicted theoretically to

338  undergo a spin transition at 40-70 GPa, but both $Fe^{3+}$ and $Fe^{2+}$ in the 8-fold-coordinated A-site

339  remain high-spin throughout the lower mantle pressure range (Hsu et al. 2010, 2011). Spin

340  transitions in $Fe^{3+}$ have been observed at various pressures in the range of 13-70 GPa by several

341  experimental studies of bridgmanite (e.g. Catalli et al. 2010, 2011; Mao et al. 2011; Lin et al.

342  2012) and other $Fe^{3+}$-bearing perovskites (Xu et al. 2001; Pasternak et al. 2002; Rozenberg et al.

343  2005). In addition, a discontinuity in volumetric compression was attributed to a spin transition in

344  6-fold-coordinated $Fe^{3+}$ in andradite garnet at 60-70 GPa (Friedrich et al. 2014). No spin

345  transition has been observed in 8-fold-coordinated $Fe^{2+}$ in pyrope-almandine garnets, but studies

346  of the equation of state and electronic configuration of these garnets have only reached ~30 GPa

347  (e.g. Mao et al. 2013).

348       In silicate glass, $Fe^{3+}$ and $Fe^{2+}$ both occupy a range of coordination environments. In

349  $MgSiO_3$ glasses, the average coordination number is 6 in the Mg-site and 4 in the Si-site, and

350  these averages increase with pressure (Funamori et al. 2004). The average coordination of Si in

351  $SiO_2$ glass has been suggested by experiments and simulations to increase stepwise or

352  continuously with compression (e.g. Meade et al. 1992). While compression alone generally

353  increases QS while decreasing IS (e.g. Pasternak et al. 2002; Kantor et al. 2006), increasing

354  coordination of Fe increases both QS and IS (Dyar et al. 2006). Observed increases in QS of $Fe^{2+}$

355  with pressure in silicate glasses have been interpreted to show densification by increasing

356  coordination number to 8-12 (Mao et al. 2014). However, in the almandine glass we observe not

357  only a slight increase in QS but an increase in broadening of the $Fe^{2+}$ site. This doublet represents

358  a superposition of multiple sites with different coordination which cannot be resolved in the

359  glass. Pressure-induced changes in Mössbauer parameters of $Fe^{2+}$ do not depend on pressure

360  medium and are thus unlikely to be due to non-hydrostatic stress. The increase in correlated

361  broadening of the $Fe^{2+}$ doublet with compression (Figure 7) suggests a broadening of the range of

362  coordination environments. The population of $Fe^{2+}$ with highest QS and IS, in higher

363  coordination, would thus increase with pressure without completely replacing $Fe^{2+}$ with lowest

364  QS and IS, in 4- to 6-fold coordination.

365  **5. Implications**

366  A sharp spin transition in iron in silicate glasses would suggest a discontinuity in the

367  properties of melt in the lower mantle or deep in a magma ocean; conversely, no sharp spin

368  transition in the glass supports a smooth variation of the properties of silicate melts with depth.

369  This study represents the first high-pressure examination of almandine glass and the first

370  combination of energy- and time-domain synchrotron Mössbauer spectra and X-ray emission

371  spectra techniques at high pressure for any silicate glass. All methods consistently support a

372  broad spin transition in $Fe^{3+}$ between 1 bar and ~30 GPa without an abrupt discontinuity. Our

373 observations differ from the previous observation of a sharp transition in Fe-bearing glass and

374 accompanying changes in solid-melt iron partitioning. We would expect that in a melt of

375 almandine composition, effects of temperature may further broaden the spin transition to a

376 greater range than the ~30-GPa interval observed in the glass. Our study supports the expectation

377 that spin transitions in iron-bearing silicate melts in Earth's mantle should be broad with respect

378 to transitions in their crystalline counterparts. No discontinuities are expected to occur under

379 compression in the density or transport properties of Fe-rich mantle melts.

380       In addition, the bonding of $Fe^{2+}$ shifts to a broader range of coordination numbers over 1

381 bar to ~60 GPa. These changes are accompanied by a change in color from transparent to black,

382 suggesting a pressure-induced reduction in radiative thermal conductivity in Fe-rich silicate

383 liquids. This increasing diversity of bonding styles may have important implications for transport

384 properties of the glass or melt network in the Earth's deep mantle or early magma ocean.

606

626 integrated relative difference (IRD) between spectra and high- and low-spin (Mg,Fe)O references

627 (Lin et al. 2010).

628 Figure 4: Energy-domain synchrotron Mössbauer spectra for almandine glass in a neon pressure

629 medium. Data are displayed as open circles. Curves are high-spin $Fe^{2+}$ doublet fit (blue), high-

630 spin $Fe^{3+}$ doublet fit (pink), low-spin $Fe^{3+}$ doublet fit (red), baseline (gray) and total fit (black).

631 Figure 5: Observed Mössbauer parameters from almandine glass. $Fe^{2+}$ component is represented

632 by two doublets in time-domain measurements (open symbols) and a single doublet with

633 correlated quadrupole splitting and isomer shift in energy-domain measurements (filled symbols).

634 Separate high- and low-spin $Fe^{3+}$ components are modeled in energy-domain measurements. a)

635 Quadrupole splitting of each doublet. Triangles joined by lines represent the two $Fe^{2+}$ sites used

636 to model the range of $Fe^{2+}$ environments in time-domain fits. b) Weight of each doublet. Two

637 $Fe^{2+}$ doublets of equal weight are used for time-domain fits.

638 Figure 6: Quadrupole splitting vs. isomer shift for silicate and inorganic glasses derived from

639 energy-domain Mössbauer spectroscopy. Literature values for glasses at ambient conditions are

640 shown in small open black squares (Dyar 1985; Virgo and Mysen 1985; Burkhard 2000). Colors

641 indicate Fe species identified at high pressure: dark blue=high-spin $Fe^{2+}$, light blue = intermediate

642 spin $Fe^{2+}$, pink=high-spin $Fe^{3+}$, red= low-spin $Fe^{3+}$. Glasses at high pressures are shown with

643 filled symbols (triangles=Prescher et al. (2014), diamonds=Murakami et al. (2014), circles= this

644 study). Arrows indicate change observed with increasing pressure.

645 Figure 7: Correlation parameter of distribution of QS and IS in fits of $Fe^{2+}$ doublet. Solid

646 symbols: compression in Ne medium. Open symbols: compression in NaCl medium.

647
